Exploratory Factor Analysis (EFA)

- Definition
  - Exploratory factor analysis (EFA) is an interdependence technique whose primary purpose is to define the underlying structure among the variables in the analysis.

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Exploratory Factor Analysis (EFA)

- Examines the interrelationships among a large number of variables and then attempts to explain them in terms of their common underlying dimensions.
- These common underlying dimensions are referred to as factors.
- A summarization and data reduction technique that does not have independent and dependent variables, but is an interdependence technique in which all variables are considered simultaneously.

Stage 1: Objectives of Factor Analysis

1. Is the objective exploratory or confirmatory?
2. Specify the unit of analysis.
3. Data summarization and/or reduction?
4. Using factor analysis with other techniques.

Factor Analysis Outcomes

- Data summarization
  - derives underlying dimensions that, when interpreted and understood, describe the data in a much smaller number of concepts than the original individual variables.
- Data reduction
  - extends the process of data summarization by deriving an empirical value (factor score or summated scale) for each dimension (factor) and then substituting this value for the original values.

Types of Factor Analysis

- Exploratory Factor Analysis (EFA)
  - is used to discover the factor structure of a construct and examine its reliability.
    It is data driven.
- Confirmatory Factor Analysis (CFA)
  - is used to confirm the fit of the hypothesized factor structure to the observed (sample) data.
    It is theory driven.

Stage 2: Designing a Factor Analysis

  1. Calculation of input data – R vs. Q analysis.
  2. Design of study in terms of number of variables, measurement properties of variables, and the type of variables.
  3. Sample size necessary.

Rules of Thumb 3–1

Factor Analysis Design

- Factor analysis is performed most often only on metric variables, although specialized methods exist for the use of dummy variables. A small number of "dummy variables" can be included in a set of metric variables that are factor analyzed.
- If a study is being designed to reveal factor structure, strive to have at least five variables for each proposed factor.
- For sample size:
  - the sample must have more observations than variables.
  - the minimum absolute sample size should be 50 observations.
- Maximize the number of observations per variable, with a minimum of five and hopefully at least ten observations per variable.

- Say positive things about XYZ to other people.
- Recommend XYZ to someone who seeks your advice.
- Encourage friends and relatives to do business with XYZ.
- Consider XYZ your first choice to buy services.
- Do more business with XYZ in the next few years.

- Three Basic Decisions

  2. Design of study in terms of number of variables, measurement properties of variables, and the type of variables.
  3. Sample size required.

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Assumptions

- Multicollinearity
  - Assessed using MSA (measure of sampling adequacy).
    - The MSA is measured by the Kaiser-Meyer-Olkin (KMO) statistic. As a measure of sampling adequacy, the KMO predicts if data are likely to factor well based on correlation and partial correlation. KMO can be used to identify which variables to drop from the factor analysis because they lack multicollinearity.
    - There is a KMO statistic for each individual variable, and their sum is the KMO overall statistic. KMO varies from 0 to 1.0. Overall KMO should be .50 or higher to proceed with factor analysis. If it is not, remove the variable with the lowest individual KMO statistic value one at a time until KMO overall rises above .50, and each individual variable KMO is above .50.
- Homogeneity of sample factor solutions

Rules of Thumb 3–2

Testing Assumptions of Factor Analysis

- There must be a strong conceptual foundation to support the assumption that a structure does exist before the factor analysis is performed.
- A statistically significant Bartlett's test of sphericity (sig. < .05) indicates that sufficient correlations exist among the variables to proceed.
- Measure of Sampling Adequacy (MSA) values must exceed .50 for both the overall test and each individual variable. Variables with values less than .50 should be omitted from the factor analysis one at a time, with the smallest one being omitted each time.

Stage 4: Deriving Factors and Assessing Overall Fit

- Selecting the factor extraction method – common vs. component analysis.
- Determining the number of factors to represent the data.

Extraction Decisions

- Which method?
  - Principal Components Analysis

- How to rotate?
  - Orthogonal or Oblique rotation

Extraction Method Determines the Types of Variance Carried into the Factor Matrix

Principal Components vs. Common?

- Two Criteria
  - Objectives of the factor analysis.
  - Amount of prior knowledge about the variance in the variables.

Number of Factors?

- A Priori Criterion
- Latent Root Criterion
- Percentage of Variance
- Scree Test Criterion

Rules of Thumb 3–3

Choosing Factor Models and Number of Factors

- Although both component and common factor analysis models yield similar results in common research settings (30 or more variables or communalities of .60 for most variables):
  - the component analysis model is most appropriate when data reduction is paramount.
  - the common factor model is best in well-specified theoretical applications.
- Any decision on the number of factors to be retained should be based on several considerations:
  - use of several stopping criteria to determine the initial number of factors to retain.
  - Factors With Eigenvalues greater than 1.0.
  - A pre-determined number of factors based on research objectives and/or prior research.
  - Enough factors to meet a specified percentage of variance explained, usually 60% or higher.
  - Factors shown by the scree test to have substantial amounts of common variance (i.e., factors before inflection point).
  - More factors when there is heterogeneity among sample subgroups.
- Consideration of several alternative solutions (one more and one less factor than the initial solution) to ensure the best structure is identified.

Processes of Factor Interpretation

- Estimate the Factor Matrix
- Factor Rotation
- Factor Interpretation
- Respecification of factor model, if needed, may involve . . .
  - Deletion of variables from analysis
  - Desire to use a different rotational approach
  - Need to extract a different number of factors
  - Desire to change method of extraction

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Rotation of Factors

- Factor rotation
  - the reference axes of the factors are turned about the origin until some other position has been reached.
    Since unrotated factor solutions extract factors based on how much variance they account for, with each subsequent factor accounting for less variance.
    The ultimate effect of rotating the factor matrix is to redistribute the variance from earlier factors to later ones to achieve a simpler, theoretically more meaningful factor pattern.

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Two Rotational Approaches

1. Orthogonal
   – axes are maintained at 90 degrees.

2. Oblique
   – axes are not maintained at 90 degrees.

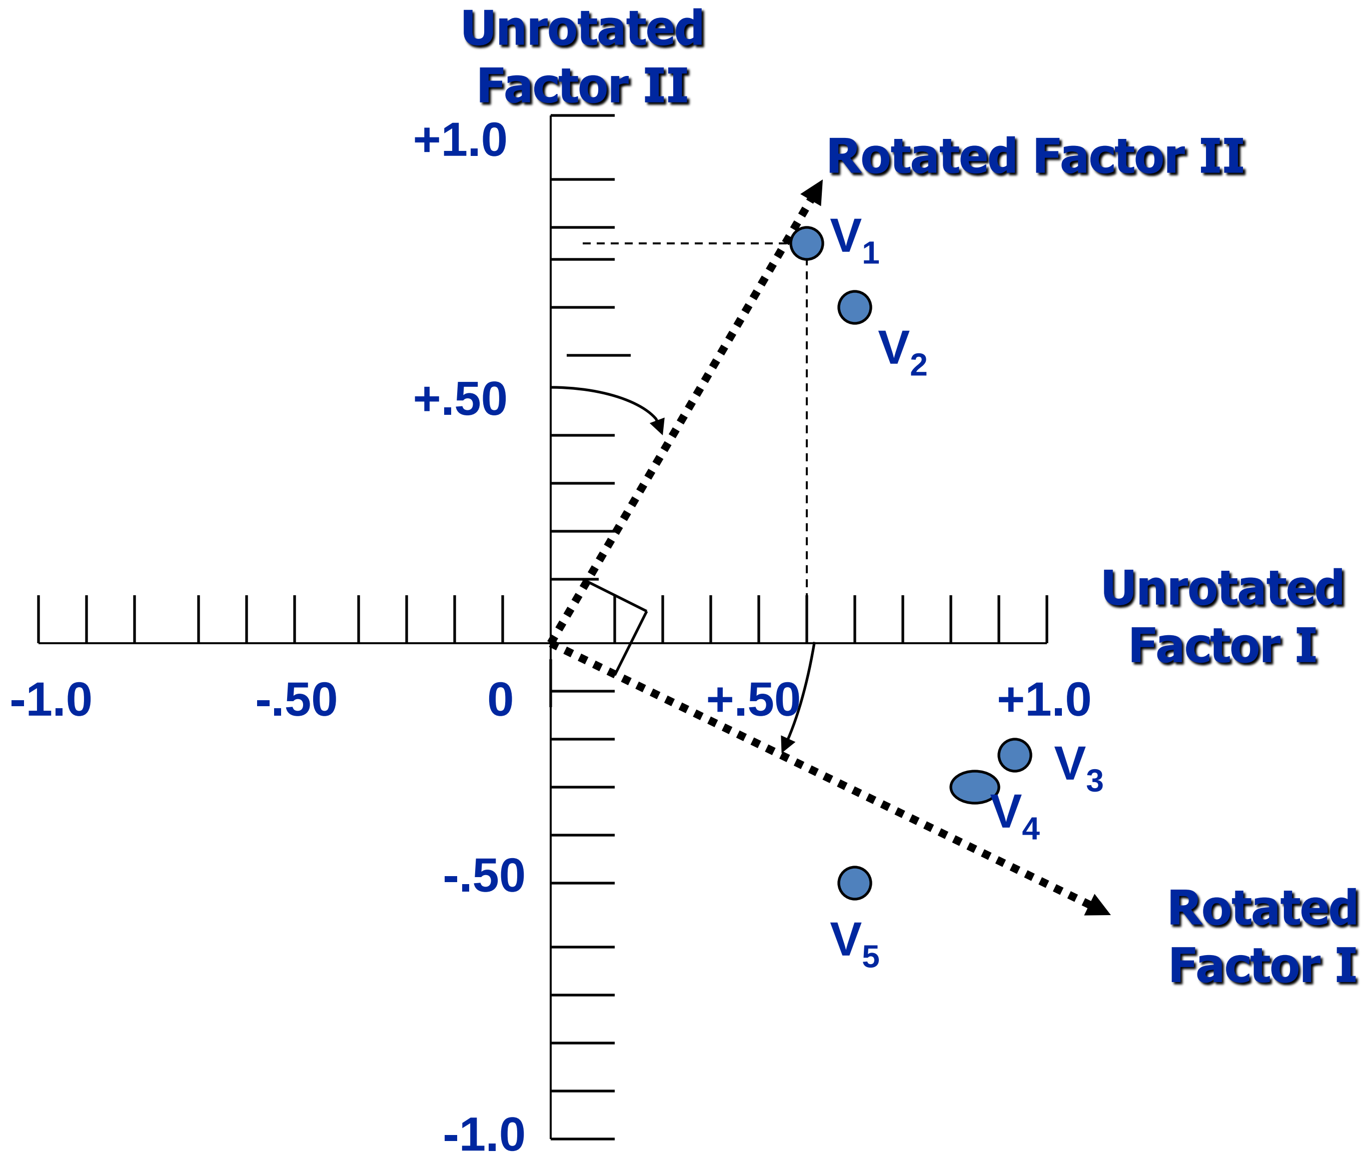
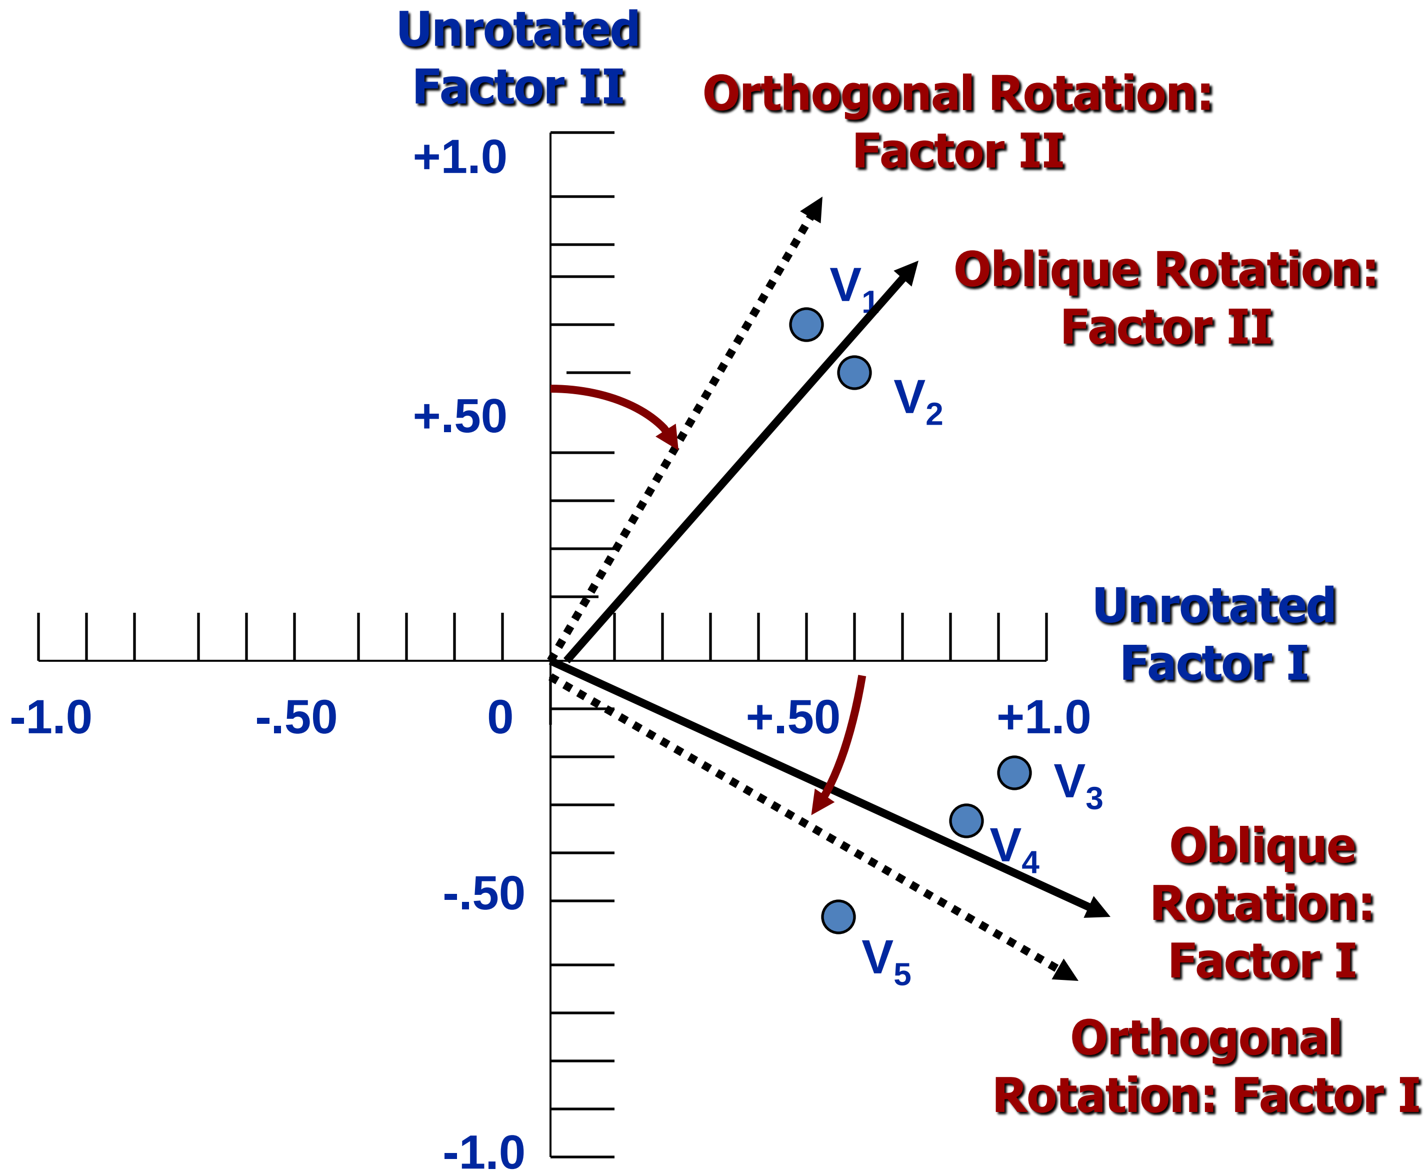
Orthogonal Factor Rotation



Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Oblique Factor Rotation



Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Orthogonal Rotation Methods

- Quartimax (simplify rows)
- Varimax (simplify columns)
- Equimax (combination)

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Rules of Thumb 3–4

Choosing Factor Rotation Methods

- Orthogonal rotation methods
  - are the most widely used rotational methods.
  - are The preferred method when the research goal is data reduction to either a smaller number of variables or a set of uncorrelated measures for subsequent use in other multivariate techniques.
- Oblique rotation methods
  - best suited to the goal of obtaining several theoretically meaningful factors or constructs because, realistically, very few constructs in the "real world" are uncorrelated

Which Factor Loadings Are Significant?

- Customary Criteria = Practical Significance.
- Sample Size & Statistical Significance.
- Number of Factors (↑ = >) and/or Variables (↑ = <) .

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Guidelines for Identifying Significant Factor Loadings Based on Sample Size

Factor Loading	Sample Size Needed for Significance*
.30	350
.35	250
.40	200
.45	150
.50	120
.55	100
.60	85
.65	70
.70	60
.75	50

*Significance is based on a .05 significance level (a), a power level of 80 percent, and standard errors assumed to be twice those of conventional correlation coefficients.

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Rules of Thumb 3–5

Assessing Factor Loadings

- While factor loadings of $\pm.30$ to $\pm.40$ are minimally acceptable, values greater than $\pm$ .50 are considered necessary for practical significance.
- To be considered significant:
  - A smaller loading is needed given either a larger sample size, or a larger number of variables being analyzed.
  - A larger loading is needed given a factor solution with a larger number of factors, especially in evaluating the loadings on later factors.
- Statistical tests of significance for factor loadings are generally very conservative and should be considered only as starting points needed for including a variable for further consideration.

Stage 5: Interpreting the Factors

- Selecting the factor extraction method – common vs. component analysis.
- Determining the number of factors to represent the data.

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Interpreting a Factor Matrix:

1. Examine the factor matrix of loadings.
2. Identify the highest loading across all factors for each variable.
3. Assess communalities of the variables.
4. Label the factors.

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Rules of Thumb 3–6

Interpreting The Factors

- An optimal structure exists when all variables have high loadings only on a single factor.
- Variables that cross-load (load highly on two or more factors) are usually deleted unless theoretically justified or the objective is strictly data reduction.
- Variables should generally have communalities of greater than .50 to be retained in the analysis.
- Respecification of a factor analysis can include options such as:
  - deleting a variable(s),
  - changing rotation methods, and/or
  - increasing or decreasing the number of factors.

Stage 7: Additional Uses of Factor Analysis Results

- Selecting Surrogate Variables
- Creating Summated Scales
- Computing Factor Scores

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Rules of Thumb 3–7

Summated Scales

- A summated scale is only as good as the items used to represent the construct. While it may pass all empirical tests, it is useless without theoretical justification.
- Never create a summated scale without first assessing its unidimensionality with exploratory or confirmatory factor analysis.
- Once a scale is deemed unidimensional, its reliability score, as measured by Cronbach's alpha:
  - should exceed a threshold of .70, although a .60 level can be used in exploratory research.
  - the threshold should be raised as the number of items increases, especially as the number of items approaches 10 or more.
- With reliability established, validity should be assessed in terms of:
  - convergent validity = scale correlates with other like scales.
  - discriminant validity = scale is sufficiently different from other related scales.
  - nomological validity = scale "predicts" as theoretically suggested.

Source: Hair et al. (2009), Multivariate Data Analysis, 7th Edition, Prentice Hall

Rules of Thumb 3–8

Representing Factor Analysis In Other Analyses

- The single surrogate variable:
  - Advantages: simple to administer and interpret.
  - Disadvantages:
    - does not represent all “facets” of a factor
    - prone to measurement error.
- Factor scores:
  - Advantages:
    - represents all variables loading on the factor,
    - best method for complete data reduction.
    - Are by default orthogonal and can avoid complications caused by multicollinearity.
  - Disadvantages:
    - interpretation more difficult since all variables contribute through loadings
    - Difficult to replicate across studies.

Rules of Thumb 3–8 (cont.)

Representing Factor Analysis In Other Analyses

- Summated scales:
  - Advantages:
    - compromise between the surrogate variable and factor score options.
    - reduces measurement error.
    - represents multiple facets of a concept.
    - easily replicated across studies.
  - Disadvantages:
    - includes only the variables that load highly on the factor and excludes those having little or marginal impact.
    - not necessarily orthogonal.
    - Require extensive analysis of reliability and validity issues.
